#### **ABSTRACT**

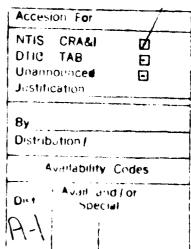

This paper stochastically models a single-node telecommunications system both with and without the use of intelligent multiplexing. Intelligent multiplexers take advantage of the idle periods or silences that occur during the course of speech transmissions to merge (or multiplex) packetized talkspurts from more than one source onto a single channel. This allows for a more efficient use of available bandwidth, thereby reducing the amount of bandwidth required to carry a particular traffic load. Digitizing speech into packets of equal size also allows for compression, further reducing bandwidth needs. By comparing the models for systems both with and without multiplexing, we are able to determine the reduction in bandwidth which may be expected for a particular grade of service (measured by blocking probabilities). A bivariate continuous time Markov chain model for a multiplexer is presented. An approximation is introduced to calculate limiting blocking probabilities much more quickly and for larger systems than is possible by solving a set of linear equations for the bivariate model. The accuracy of the approximation is explored through comparison with the bivariate model; the approximation provides a somewhat conservative estimate of blocking, but is close enough to be used as a tool for the range of relevant values. The approximation is then used to compare blocking probabilities for three different levels of speech activity. Results are shown in tabular form.

#### THESIS DISCLAIMER

The reader is cautioned that computer programs developed in this research may not have been exercised for all cases of interest. While every effort has been made, within the time available, to ensure that the programs are free of computational and logic errors, they cannot be considered validated. Any application of these programs without additional verification is at the risk of the user.

#### I. INTRODUCTION

The field of telecommunications has been advancing at a tremendous rate in recent years, assisted by the decreasing costs and increasing capability of microprocessors, as well as by deregulation of the industry. New products and capabilities are coming online at an astounding rate. It has become commonplace to transport data between computers with the use of modems along standard telephone lines at ever-increasing baud rates. More companies every day are opting to use video-conferencing as a replacement for time-consuming travel to business meetings. Fax machines are now priced for use in the home as well as in the office. Cellular phones for use in automobiles and airplanes make "getting away from it all" more difficult than ever. The latest sensation to hit the consumer market is a telephone with video screen to view the person on the other end of the phone line (if they have the same device, of course), also priced for home use. There seems to be no limit to the potential market for increasingly sophisticated (i.e. bandwidth intensive) telecommunications products.

In order to provide economical transmission of high bandwidth data, such as fax and video, it has become increasingly important to find inexpensive ways to increase bandwidth and to conserve the bandwidth available. A variety of technical innovations, such as fiber optic networks, data compression techniques, and multiplexers, have been developed to do just that.

#### A. WHAT IS MULTIPLEXING?

Multiplexing techniques are designed to reduce bandwidth needs, thereby reducing costs, by sharing bandwidth among network users. Intelligent multiplexers accomplish this by sending the packetized information from a large number of channels onto a single wideband channel, without transmitting any of the silent periods. This achieves very high utilization rates along the single channel.

Intelligent multiplexers take advantage of the idle times that occur during the course of any telecommunications transmission to make more efficient use of available bandwidth. Speech conversations, for instance, are silent about 60% of the time; when one person is speaking, the other is normally silent and listens. Also, there are pauses between words and sentences. Data traffic often averages only 5-15% efficiency, tending to be bursty, occurring for a short time, then subsiding to occur some undetermined time later. These bursts of data traffic also have high bandwidth requirements.

There are two basic types of intelligent multiplexer on the market. The older of the two is referred to as statistical time-division multiplexing (STDM) or statistical packet multiplexing (SPM); the newer is called fast packet multiplexing (FPM). They are both microprocessor-based, meaning both higher efficiency and higher cost when compared with frequency division multiplexing and time division multiplexing. These newer technologies will consequently only begin to replace what is already in use as microprocessor price/performance ratios improve enough to justify the efficiency gains.

#### **B. STANDARDS**

Due to the current lack of standards for intelligent multiplexing equipment, manufacturers have each designed their own intermachine communication systems, and no two systems are compatible. This creates problems when users of private networks want to tap into another private or public network. It can also make direct comparisons among various vendor products difficult for the potential buyer.

Standards bodies, such as the American National Standards Institute (ANSI), the International Telegraph and Telephone Consultative Committee (CCITT), and the Institute of Electrical and Electronic Engineers (IEEE), are working on standards for equipment which will likely supersede current multiplexer technology. Standards seem to be evolving in the direction of transmitting all information (speech, data, video, etc.) in the form of packets or "cells."

#### C. DEFENSE COMMUNICATIONS AGENCY INTEREST

The Defense Communications Agency (DCA) is extremely interested in exploring the capabilities of these new and emerging technologies in order to plan ahead for changes to MILDEP networks. Studies are ongoing to assess the various intelligent or "smart" multiplexer products on the market and to determine criteria on which to base future purchasing decisions [Ref. 1: pp. 1-23].

In the Advanced Design Group, headed by Dr. Martin Fischer, the inclusion of intelligent multiplexers (smart mux or smux) will affect the network topology design tools currently being developed. The key question for them, regarding the smart mux, is how much of a reduction in bandwidth

can be obtained by the use of intelligent multiplexers while maintaining current network performance levels. Their data base contains bandwidth costs based on AT&T tariffs as well as the cost data for several different brands of multiplexer. They also know how many channels are required to carry a particular traffic load, expressed in Erlangs, without the use of a smart multiplexer. A simple way to calculate the reduction in channels needed when multiplexers are added to the network would allow them to do comparative cost analyses.

#### D. PURPOSE OF THIS STUDY

The purpose of this study is to find a simple, yet relatively accurate, way to determine the reduction in bandwidth which will result from adding intelligent multiplexers to a voice network. It will involve stochastically modeling a single node of a communications network, both with and without a multiplexer. Approximations to the more complicated stochastic model are then studied.

In the next section we provided a summary of the technology. In Section III we review some of the relevant literature. Section IV presents a description of the models studied, while Section V covers the approximation techniques used to compute limiting probabilities for those models. In Section VI we describe the programs used to perform the calculations and the validation techniques for the computer code. In Sections VII and VIII we discuss the numerical results and conclusions, respectively.

#### II. DESCRIPTION OF THE TECHNOLOGY

#### A. FREQUENCY DIVISION MULTIPLEXING

The oldest multiplexing technique is frequency division multiplexing (FDM). FDM divides the frequency spectrum of analog circuits into smaller narrowband segments. The narrowband implementation limits the data rates which can be used for remote networking [Ref. 2: p. 54].

#### B. TIME DIVISION MULTIPLEXING

Time division multiplexing (TDM), which began to replace FDM when remote network data rates increased above 2400 bits per second (bps), divides the communication link into a fived number of time slots. Each slot is assigned to a specific channel. Transmission occurs in a regular sequence, cycling through the channels. Bandwidth allocation is fixed, and is based on the size of the time slot allocated to each channel. TDM is relatively inexpensive to implement and introduces very little delay. However, TDM is not very efficient in the use of bandwidth. If a channel is idle, that time slot is not available for use by any other channel. Also, the silent periods of a voice or data transmission go unused. For combined voice and data traffic, TDM averages only 10-25% efficiency. TDM is unable to momentarily increase bandwidth for high-speed data due to the fixed time slots and bit rates. Thus, TDM is not well-suited to transporting a dynamically varying combination of voice, fax, and LAN traffic [Ref. 2: p. 54].

#### C. STATISTICAL PACKET MULTIPLEXING

Statistical packet multiplexing solves both of the problems associated with TDM, that is, network efficiency and ability to dynamically allocate bandwidth, but has two drawbacks of its own. It introduces higher network delay and difficulty in predicting the amount of delay. Thus, SPM is not suited for time-sensitive information, such as voice and video traffic.

Instead of statically dividing the network bandwidth as in TDM, SPM dynamically allocates bandwidth to those channels passing data at the moment. Within the multiplexer (mux), SPM operates by gathering transmitted data from the active channel into a packet, appending identifying and control information, and passing the packet to the next multiplexer. The next mux checks for transmission errors (using the control information) and requests retransmission if errors are found. Any errors are corrected before the packet is sent on. The packetization of data also allows the originating multiplexer to easily perform various operations on the data, such as encryption and compression.

Due to the different advantages and disadvantages associated with both TDM and SPM, many networks in use today are hybrids that combine the two. TDM is used for time-sensitive information (voice, video, some synchronous data and LAN traffic) while SPM is used where higher network efficiency and dynamic bandwidth allocation are important (primarily asynchronous data, and some synchronous data and LAN traffic) [Ref. 2: p.55].

Descriptions of the first three multiplexing techniques may be found in references [Ref. 2: pp. 54-55, Ref. 3: pp. 112-113, and Ref. 4: pp. 165-188].

#### D. FAST PACKET MULTIPLEXING

Fast packet multiplexing (FPM) is a generic term for remote networking techniques that satisfy the following criteria [Ref. 2:p. 54]:

- the ability to transport a dynamically varying combination of voice, fax, video, synchronous data, asynchronous data, and LAN (local area network) traffic;
- high network efficiency, typically 90% or better;
- low network delay;
- predictable delivery of time-sensitive information.

Fast packet multiplexing is the most recent of four main multiplexing techniques designed for use in telecommunications networks. It is very similar to statistical packet multiplexing. As with previous multiplexing techniques, it is a way to reduce bandwidth needs by sharing bandwidth among network users, thereby reducing costs.

Unlike the other multiplexing techniques, it is designed to efficiently transmit a wide variety of time-sensitive information along the same network.

FPM has the following characteristics [Ref. 2:pp. 56-59]:

- it gathers each incoming channel's data into equal size cells (packets) for delivery over the network;
- it begins to forward cells of a message before all cells are completely received; i.e. cells pass through the FPM device rather than into and then out of the device;
- it can interrupt the delivery of one channel's message in favor of delivering a more time-sensitive (i.e. higher priority) channel's message (using cell boundaries to determine where interruptions may occur);
- the time it takes to transmit a cell is directly related to both the cell size and the bit rate of the network (outgoing) link; low rates and large cell size increase transmission time. The cell size is fixed by making it

- proportional to the bit rate of the network link. Since cell sizes and bit rates of the links are fixed, service times for each cell are equal;
- it eliminates idle bandwidth from the incoming channels and transmits only active information, so more calls can be in progress than the number of physical channels available.

#### III. LITERATURE REVIEW

#### A. QUEUEING THEORY

#### 1. The Erlang B (Loss) Formula

Voice communication systems using time-division multiplexing are often modeled stochastically as queueing models, using the Erlang loss system [Ref. 5:pp. 79-81]. Here, it is assumed that calls are initiated according to a Poisson process with rate  $\lambda$ , service times are exponentially distributed with mean length  $\mu^{-1}$ , independent of each other and the arrival process; and if all servers (channels) are busy when a customer (caller) arrives, that customer cannot enter the system (gets a busy signal); that is, blocked customers are cleared (BCC). The ratio  $\lambda/\mu$  is the offered load a, expressed in Erlangs. For a given number of channels c, the limiting probability of j busy channels is given by the truncated Poisson distribution:

$$\lim_{t \to \infty} P_j(t) = P_j = \frac{\frac{\left(\lambda/\mu\right)^j}{j!}}{\sum_{k=0}^c \frac{\left(\lambda/\mu\right)^k}{k!}} \quad (j = 0, 1, \dots c)$$
 (1)

This formulation is also found in Ross [Ref. 6:p. 390].

The proportion of time that all c channels are busy is calculated by the Erlang B formula (or Erlang loss formula)

$$B(c,a) = \frac{a^{c}/c!}{\sum_{k=0}^{c} a^{k}/k!},$$
 where  $a = \lambda/\mu$ . (2)

This formula is used to determine the number of channels c needed to achieve a particular blocking probability B(c,a), given the offered load a in Erlangs. By plotting the Erlang loss formula B(c,a) against increasing values of a, curves for fixed values of c are obtained [Ref. 5:pp. 316-317]. Tables of these values have also been created. The carried load a' is also easily calculated:

$$a' = a [1 - B(c_A)].$$
 (3)

This is part of the method currently in use at DCA to determine the number of channels required along any particular trunk in the network modeling process for a given load.

#### B. MULTIPLEXER MODELS

Numerous models for various types of multiplexer have been developed. Similar models are used to analyze both computer and communication networks. A data-handling computer network is modeled by Anick, Mitra, and Sondhi [Ref. 7:pp. 1871-1894] using differential equations to describe the equilibrium buffer distribution. The model is used to determine the appropriate buffer size for a particular number of sources and grade of service. It is also used to determine the maximum number of sources to be allowed in the system. Integrated voice-data multiplexers are modeled in references [Ref. 8:pp. 8-14, Ref. 9:pp. 1124-1132, Ref. 10:pp. 833-846, and Ref. 11:pp. 1003-1009]. The first reference [Ref. 8:pp. 8-14] uses a continous-time queueing model which models performance of a flow control scheme for a movable boundary voice-data multiplexer and develops a decision rule based on data queue length to cutoff the priority of voice. Reference [Ref. 9:pp. 1124-1132] compares

two different voice-data multiplexer schemes, both of which use the movable boundary frame allocation scheme. The second scheme uses speech activity detectors (SAD's) so that the multiplexer also performs digital speech interpolation. This allows utilization of talker silences for transmission of additional voice and/or data. Performance measures include: probability of loss for voice calls, probability of speech clipping, speech packet rejection ratio, and expected message delay. The third reference [Ref. 10:pp. 833-846] uses the index of dispersion for intervals (IDI) as a measurement tool to characterize the complex arrival process resulting from superposition of separate voice streams. The paper also describes delays experienced by voice and data packets using a two-parameter approximation. The fourth reference [Ref. 11:pp. 1003-1009] models wideband packet technology integrating packetized voice and data using statistical multiplexing. It incorporates a flexible bandwidth allocation scheme with bit dropping; results using simulation show good voice quality, low delay and packet loss, efficient use of transmission bandwidth, and protection in overload. References [Ref. 12:pp. 847-855, Ref. 13:pp. 41-56, Ref. 14:pp. 703-712, and Ref. 15:pp. 718-728] all model packet voice multiplexers. Reference [Ref. 12:pp. 847-855] describes three models; a semi-Markov process, a continuous-time Markov chain, and a uniform arrival and service model; then compares numerical results of the queueing behavior of the three models to each other and to a discrete-event simulation and an M/D/1 analysis. All models assume multiple independent voice sources which form a queue for first-in-first-out (FIFO) service along a finite-capacity communications link. The second reference [Ref. 13:pp. 41-56] develops methodologies for evaluating the performance of variable bit rate voice under the following two conditions: (1) at a fixed load when instantaneous fluctuations occur due to talker activity/inactivity and (2) under variable load when variations occur due to call on/off. The authors use a Markov chain model in conjunction with a software package to emulate packetized voice and describe the probabilistic bit-dropping pattern under various loading and traffic conditions. The third reference [Ref. 14:pp. 703-712] uses simulation and analytic modeling (M/D/1/K) to examine performance of a packet voice multiplexer queue which employs bit dropping during periods of congestion. Results indicate that significant capacity and performance advantages are gained in the multiplexer as a result of dropping the least significant bits when the system is congested. The fourth reference [Ref. 15:pp. 718-728] also uses an M/D/1/K queueing model for measuring performance of a voice packet network which uses bit dropping.

For purposes of this paper we have chosen a model which allows no queue to develop (blocked customers are cleared). Rather, we focus on the proportion of time that blocking occurs. That is, we assume that voice calls are so time-sensitive that no waiting time can be tolerated, so they are dropped (denied transmission) to avoid congestion. This is not a completely accurate description of what occurs in the multiplexer, however, we hope that it provides an adequate, albeit conservative approach.

#### IV. MODEL DEVELOPMENT

#### A. THE ERLANG MODEL

The first step toward developing the multiplexer model is to enhance the Erlang model with the addition of talkspurts. This will be used as a basis for the multiplexer model and also as a comparison model by which to measure the relative performance increase once a multiplexer is added.

#### 1. Variables

In what follows, the following variables were used:

- C(t) is used to represent the number of calls in progress at time t.
- A(t) is used to represent the number of talkspurts (active calls) at time t.

K is the maximum number of calls allowed (= the number of channels).

Lambda ( $\lambda$ ) is the call initiation rate (in call initiations per second).

Mu  $(\mu)$  is the call termination rate (in call terminations per second).

 $\mu^{-1}$  is the mean time (in seconds) that a call is in progress.

Alpha ( $\alpha$ ) is the talkspurt initiation rate (in initiations per second).

Beta  $(\beta)$  is the talkspurt termination rate (in terminations per second).

 $\alpha^{-1}$  is the mean length of a silent period (in seconds).

 $\beta^{-1}$  is the mean time (in seconds) of talkspurt duration.

- $\alpha/(\alpha+\beta)$  is the proportion of time that a call in progress of infinite duration is active.
- $\beta/(\alpha + \beta)$  is the proportion of time that a call in progress of infinite duration is silent.

#### 2. Model Assumptions

It is assumed that calls are initiated in accordance with a Poisson process with mean rate  $\lambda$ . The length of a call in progress is exponential with mean  $\mu^{-1}$ . Blocked calls (customers) are cleared; that is, new calls are prevented from initiation if all available channels are in use. Let  $\{C(t); t \geq 0\}$  be the number of calls in progress at time t.

Calls in progress alternate between active and inactive states as talkspurts are initiated and terminated. We model this process as an alternating renewal process where the length of the talkspurt is exponential with mean  $\beta^{-1}$  and the length of a silent period is exponential with mean  $\alpha^{-1}$ . Let  $\{A(t); t \geq 0\}$  be the number of calls in progress that are active at time t. Note that  $A(t) \leq C(t)$ .

It is also assumed that when a new call is initiated, it is immediately active; that is, a talkspurt is simultaneously initiated. When a call terminates, it may do so from either an active or inactive state.

#### 3. Description

The model is a two-dimensional birth-and-death queueing model. It maintains the Markov property inherent in one-dimensional birth-and-death queueing systems, i.e the system occupies "states," and the rates at which changes of state occur depend only on the instantaneous state of the system and not on the past history of the process. However, two variables are required to define the state space. The bivariate process  $\{(C(t), A(t)); t \ge 0\}$  is a continuous time Markov chain with the following:

$$\begin{split} P\{C(t+h) = c, \ A(t+h) = a \ | \ C(t) = k, \ A(t) = j\} \\ &= [\lambda h + o(h)] \ I(j \le k) \ I(k < K) & \text{if} \quad c = k+1, \ a = j+1, \\ &= [(k-j)\alpha h + o(h)] \ I(j < k) & \text{if} \quad c = k, \ a = j+1, \\ &= [j\beta h + o(h)] \ I(j \le k) \ I(j > 0) & \text{if} \quad c = k, \ a = j-1, \\ &= [\mu j h + o(h)] \ I(k > 0) \ I(j > 0) \ I(j \le k) & \text{if} \quad c = k-1, \ a = j-1, \\ &= [\mu (k-j)h + o(h)] \ I(j > 0) \ I(j \le k) & \text{if} \quad c = k, \ a = j-1, \\ &= 0 & \text{otherwise,} \end{split}$$

where 
$$I(x < y) = \begin{cases} 1 \text{ if } x < y \\ 0 \text{ if } x \ge y \end{cases}$$
.

A rate diagram for this model, where the maximum number of available channels is three, is shown below in Figure 1; see [Ref. 6:p. 360] for discussion of transition rate diagrams.

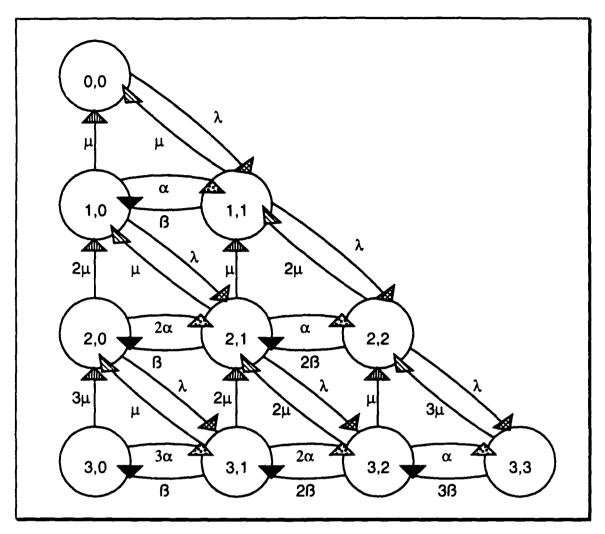

Figure 1. Graphical Representation of Three-Channel Bivariate Erlang System

Conservation-of-flow ("rate out = rate in") equations may be used to describe the system in equilibrium [Ref. 5:pp. 3-4]. We let the  $\lim_{t\to\infty} P\{C(t)=k, A(t)=j\}=\Pi\{k,j\}$ , where (k=0,1,...,K) and (j=0,1,...,k) represent the limiting distribution. The conservation-of-flow equations, which equate the rate the system leaves each state to the rate at which it enters that state, are shown below for a system with three available channels:

$$\lambda\Pi\{0,0\} = \mu\Pi\{1,0\} + \mu\Pi\{1,1\},$$

$$(\alpha + \lambda + \mu)\Pi\{1,0\} = \beta\Pi\{1,1\} + 2\mu\Pi\{2,0\} + \mu\Pi\{2,1\},$$

$$(\beta + \lambda + \mu)\Pi\{1,1\} = \lambda\Pi\{0,0\} + \alpha\Pi\{1,0\} + \mu\Pi\{2,1\} + 2\mu\Pi\{2,2\},$$

$$(2\alpha + \lambda + 2\mu)\Pi\{2,0\} = \beta\Pi\{2,1\} + 3\mu\Pi\{3,0\} + \mu\Pi\{3,1\},$$

$$(\alpha + \beta + \lambda + 2\mu)\Pi\{2,1\} = \lambda\Pi\{1,0\} + 2\alpha\Pi\{2,0\} + 2\beta\Pi\{2,2\} + 2\mu\Pi\{3,1\} + 2\mu\Pi\{3,2\},$$

$$(2!_{-} + \lambda + 2\mu)\Pi\{2,2\} = \lambda\Pi\{1,1\} + \alpha\Pi\{2,1\} + \mu\Pi\{3,2\} + 3\mu\Pi\{3,3\},$$

$$(3\alpha + 3\mu)\Pi\{3,0\} = \beta\Pi\{3,1\},$$

$$(2\alpha + \beta + 3\mu)\Pi\{3,1\} = \lambda\Pi\{2,0\} + 3\alpha\Pi\{3,0\} + 2\beta\Pi\{3,2\},$$

$$(\alpha + 2\beta + 3\mu)\Pi\{3,2\} = \lambda\Pi\{2,1\} + 2\alpha\Pi\{3,1\} + 3\beta\Pi\{3,3\},$$

$$(3\beta + 3\mu)\Pi\{3,3\} = \lambda\Pi\{2,2\} + \alpha\Pi\{3,2\}.$$

The sum of the terms on the left-hand side (rates out) is equal to the sum of the terms on the right-hand side (rates in). Any one of these equations is, thus, redundant and may be ignored. The remaining equations, along with the normalization equation

$$\sum_{k=0}^{3} \sum_{j=0}^{k} \Pi\{k, j\} = 1,$$

uniquely determine the limiting probabilities.

#### 4. Parameter Values

If the average length of a phone call  $(\mu^{-1})$  is taken to be 180 seconds (three minutes), then  $\mu$  = 1+180. The length of a talkspurt  $(\beta^{-1})$  must be shorter than the length of a phone call for the model to be reasonable. We also want to maintain the proper proportion between the length of talkspurts and silent periods. Speech activity ranges from 28% to 42% depending on

cultural and language characteristics of the user population [Ref. 16:p. 1]. If voice conversations are assumed silent 60% of the time, then we need to have  $\beta+(\alpha+\beta)=0.60$ . The input value for  $\lambda$  is treated as variable; increasing the value of  $\lambda$  corresponds to an increasing load on the system, where load is defined to be  $\lambda+\mu$ . Increasing the load increases the blocking probability. The maximum number of channels is also treated as variable. Increasing the number of channels decreases the blocking probability.

#### B. THE MULTIPLEXER MODEL

The multiplexer model begins with the Erlang model as described above, then adds the three main features which are characteristic of how a multiplexer functions. The first and most important distinguishing characteristic of the multiplexer is that it allows more calls in progress than the actual physical number of channels. This is accomplished by taking advantage of the silent periods in each conversation to merge together packetized talkspurts from multiple conversations. Secondly, it compresses the packetized talkspurt to a fraction of its original length. Third, and lastly, it appends header information to each packet, to allow the talkspurt to be recreated at the destination node. See [Ref. 17:p. 430] for additional discussion of the information contained in the packet header.

#### 1. Variables

The following are additional variables that appear in the multiplexer model. A new variable (J) is added, and the value of K is redefined. Also,  $\beta^{-1}$  is replaced by  $(\beta^{-1})^*$ , and service rate (s) is added.

J is the maximum number of talkspurts allowed (equal to the number of physical channels).

K is the maximum number of calls allowed to be in progress (may be several times greater than J).

 $(\beta^{-1})^*$  is the new mean talkspurt length in units of bits per talkspurt after compression and addition of packet headers.

b is the number of bits per second produced by the coding scheme.

s, the service rate in bits per second, is simply the outgoing channel rate (of the wideband channel).

 $\beta^*$ s is the new departure or service rate of talkspurts (in talkspurts per second), where  $\beta^*$  is the inverse of  $(\beta^{-1})^*$ .

#### 2. Additional Model Assumptions for the Multiplexer Model

Although more calls than channels are allowed, new calls are blocked when the number of active calls in progress (talkspurts) equals the number of available channels. Voice packets belonging to a call in progress are also blocked (lost or "clipped") when the number of active calls in progress equals the number of available channels.

#### 3. Description

In the multiplexer, all talkspurts from all incoming channels flow through a buffer, where they are "packetized" and sent forward along a single wideband channel. The multiplexer divides talkspurts into fixed size packets and attaches certain header information that allows the talkspurt to be reconstructed at the destination node by a demultiplexer. The multiplexer can also compress the packetized information so that it uses fewer bits, thus occupying less space as it moves through the channel. Typical compression schemes use either a 2-to-1 or 4-to-1 rate of compression.

The intelligent multiplexer model is also a bivariate process  $\{(C(t), A(t)); t \ge 0\}$  and a continuous-time Markov chain with the following:

where 
$$I(x < y) = \begin{cases} 1 & \text{if } x < y \\ 0 & \text{if } x \ge y \end{cases}$$
.

A rate diagram for the multiplexer model, where the maximum number of available channels is three, is shown below in Figure 2; see [Ref. 6:p. 360] for discussion of transition rate diagrams.

In the multiplexer model, there can be two types of blocking. Outside calls can be blocked from initiation (external blocking) and calls in progress can be blocked from transmitting a talkspurt (internal blocking). Both kinds of blocking occur when the number of talkspurts (active calls) is at the line capacity

$$\lim_{t\to\infty} P\{A(t)=J\} = \sum_{k=J}^K \lim_{t\to\infty} P\{C(t)=k, A(t)=J\}.$$

The blocking of calls from initiation also occurs when the number of calls in progress is at the maximum allowed (C(t)=K). The proportion of time this occurs is given by

$$\lim_{t \to \infty} P\{C(t) = K\} = \sum_{j=0}^{J} \lim_{t \to \infty} P\{C(t) = K, A(t) = j\}.$$

In comparison, blocking in the Erlang model occurs only when the number of calls in progress equals the number of physical channels. There is

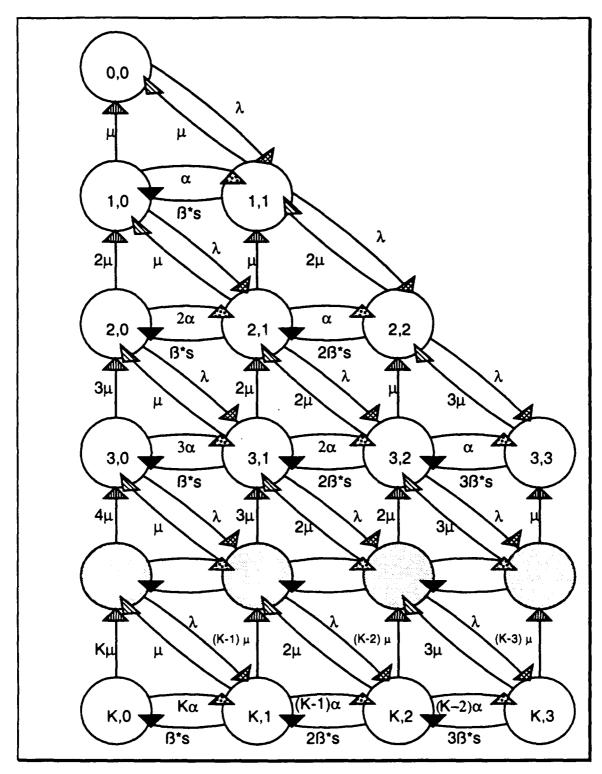

Figure 2. Graphical Representation of Three-Channel Smart Mux Model

no internal blocking. Note that under reasonable loading it is possible for  $A(t) \le J \le C(t) \le K$ , where J is the maximum number of active calls that the transmission line can support and K is the maximum number of calls allowed in the system. For purposes of this paper, we will refer to the external blocking that occurs when C(t)=K as outer blocking. The internal and external blocking that occurs when A(t)=J will be called inner blocking. By adding the two together and subtracting out the joint limiting probability that  $\{C(t)=K, A(t)=J\}$ , we get the total probability of blocking.

#### D. PARAMETER VALUES

The value for length of talkspurts ( $\beta^{-1}$ ) in the Erlang model changes in the multiplexer case to account for both compression of the packetized talkspurt and for header information appended to each packet. Packet lengths are expressed in terms of bits rather than time, but can be converted to units of time if given the line rate of the transmission medium in terms of bits per second (bps). The voice packet size depends on the coding scheme used. For 32 Kbps, ADPCM coding, and a packetization period of T=16 milliseconds (ms), the packet size is 512 bits or 64 bytes (there are 8 bits per byte), plus a header [Ref. 16:p. 1]. A talkspurt of 352 ms is divided into 352+16 = 22 packets and contains a total of 11264 bits (1408 bytes). Each packet is then compressed. A compression factor of four reduces each packet to 128 bits. Appending a packet header of 10 bytes to each compressed packet increases the length to 208 bits (26 bytes). Thus the number of bits in a talkspurt of 352 ms is 4576 after compression and addition of headers. This compression and addition of packet headers to alter the original mean talkspurt length,  $\beta^{-1}$  (in units of

seconds), results in the new mean talkspurt length in units of bits,  $(\beta^{-1})^*$ , defined in the multiplexer model as follows:

$$(\beta^{-1})^* = \beta^{-1} \times T^{-1} \times (\text{\# bits/packet}) \times ((1 + \text{compress}) + \text{header proportion})$$
  
=  $\beta^{-1} \times b \times ((1 + \text{compress}) + \text{header proportion})$ 

= number of bits per average talkspurt,

where b, the number of bits per second produced by the coding scheme, is equivalent to the number of bits per packet (e.g. 512) divided by the packetization period T (e.g. 16 ms per packet). Also note that  $\beta^{-1} \times T^{-1}$  is equal to the mean number of packets in a talkspurt.

Compress is set equal to four (4) to indicate a 4-to-1 compression of data by the multiplexer. Packet header information is assumed to be 10 bytes (attached to a 64 byte packet), [Ref. 16], for a header proportion of 10+64 = .15625.

In addition, the service rate of the outgoing channel is now many times larger than any of the incoming channels. The Defense Communications Agency commonly uses T1 lines, which carry 1.544 Mbps (1.536 Mbps after accounting for the signalling channel). The T1 lines may be divided into 1.536 Mbps+32 Kbps = 48 separate channels. Therefore the outgoing T1 rate is 48 times larger than the rate of the encoding scheme. A talkspurt of 352 ms (without compression and addition of packet header) will take 11264 bits+1.536 Mbps = 0.073 ms to transmit on a T1 line.

In this multiplexer model, however, we do not necessarily want to assume full T1 rates for the outgoing channel. Rather, we need to be able to look at fractional T1 rates for lighter traffic loads, so we assume that the outgoing rate is equal to 32 Kbps multiplied by the maximum number of

active calls allowed (labeled J in the multiplexer model described above; labeled A in the computer code). The incoming channel rate is set equal to b=32 Kbps. The ratio of the outgoing channel rate to the rate of an active incoming channel is set equal to J. In the multiplexer model,  $J \times b$  is defined as the service rate, s. The termination rate for talkspurts in the multiplexer model is given by  $\beta^*s$ .

#### V. APPROXIMATIONS

#### A. THE ERLANG MODEL APPROXIMATION

As noted earlier, the truncated Poisson formula is used to calculate the limiting probabilities for an Erlang loss system with maximum K channels and input parameters  $\lambda$  and  $\mu$ ; that is, a model for the calls in progress  $\{C(t); t \geq 0\}$  is a continuous time Markov chain with transition rate diagram shown in Figure 3 [Ref. 6:p. 360].

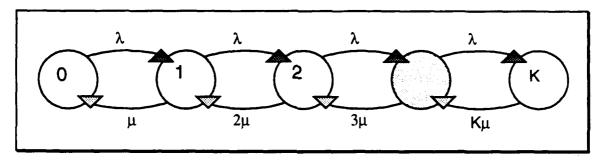

Figure 3. Transition Rate Diagram for Calls in Progress

To deal with the bivariate Erlang system, we need to consider the two additional parameters ( $\alpha$  and  $\beta$ ) which describe talkspurt initiation and termination. Fix the number of calls in progress equal to  $k \le K$ . A model for the number of active calls in progress is a continuous time Markov chain with the rate diagram shown in Figure 4. Since the calls in progress are independent of each other, the limiting distribution of having j active calls is described by the binomial distribution;

$$\lim_{t \to \infty} P\{A(t) = j | k \text{ calls in progress}\} = {k \choose j} \left(\frac{\alpha}{\alpha + \beta}\right)^j \left(\frac{\beta}{\alpha + \beta}\right)^{k-j}.$$
 (4)

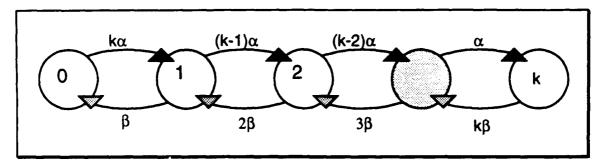

Figure 4. Transition Rate Diagram for Active Calls in Progress

Limiting probabilities for the bivariate Erlang system can be approximated by combining the truncated Poisson distribution (1) with the binomial;

$$\lim_{t \to \infty} P\{A(t) = j, C(t) = k\} = \frac{\frac{(\lambda/\mu)^k}{k!}}{\sum_{t=0}^K \frac{(\lambda/\mu)^t}{i!}} {k \choose j} \left(\frac{\alpha}{\alpha+\beta}\right)^j \left(\frac{\beta}{\alpha+\beta}\right)^{k-j},$$
 (5)

where (k = 0,1,..., K) and (j = 0,1,..., k).

#### B. THE MULTIPLEXER MODEL APPROXIMATION

For the multiplexer model, the binomial probability of having j talkspurts, given k calls in progress, must be adjusted to reflect the new restriction that the number of talkspurts cannot exceed the number of physical channels J, and that J may be less than k. The following form of the truncated binomial [Ref. 5:p. 109] was used rather than the binomial distribution used in the Erlang model.

$$P_{j}(k) = \lim_{t \to \infty} P\{A(t) = j | k \text{ calls always in progress}\} = {k \choose j} \left(\frac{\alpha}{\beta * s}\right)^{j} P_{0}(k),$$

$$where P_{0}(k) = \left[\sum_{i=0}^{J} {k \choose j} \left(\frac{\alpha}{\beta * s}\right)^{j}\right]^{-1}$$
(6)

for  $j \le k$ , where (k = 0, 1, ..., K) and (j = 0, 1, ..., J).

The truncated Poisson distribution (1) is still used to find the probability of k calls in progress (k=0,1...,K), but now it yields an approximate rather than an actual limiting probability, since it fails to account for the additional internal blocking in the multiplexer model. Thus, the truncated Poisson yields a conservative estimate of the external blocking that occurs when the maximum allowed number of calls are in progress (outer blocking).

The joint approximate limiting probabilities for the multiplexer model are similarly found by multiplying the truncated Poisson by the truncated binomial; that is,

$$\lim_{t \to \infty} P\{C(t) = k, A(t) = j\} = \left[\frac{\frac{(\lambda/\mu)^k}{k!}}{\sum_{k=0}^K \frac{(\lambda/\mu)^k}{k!}} \left[\frac{\binom{k}{j} \left(\frac{\alpha}{\beta * s}\right)^j}{\sum_{j=0}^J \binom{k}{j} \left(\frac{\alpha}{\beta * s}\right)^j}\right],$$
(7)

for  $j \le k$ , where (k = 0,1,...,K) and (j = 0,1,...,J).

#### VI. SOLUTION TECHNIQUES

#### A. SOLVING SETS OF LINEAR EQUATIONS

Two programs were written to solve the system of linear equations determining the limiting distribution (for both the Erlang and the multiplexer models). One uses GAMS [Ref. 18], which is a software package developed to solve large mathematical (linear and non-linear) programming models. The other uses APL to solve the system of equations through matrix inversion and was developed by Professor Patricia Jacobs of the Naval Postgraduate School. The GAMS programs may be found in Appendix A (Erlang model) and Appendix B (multiplexer model). The APL program for the multiplexer model, in Appendix C, may also be used to solve the Erlangian system with some adjustments to the input variables.

This solution technique, though accurate, was found to be useful only for small problems. Using an IBM mainframe computer, the GAMS programs were solvable for systems of about 15 channels in the Erlang model (with a load of 15 Erlangs). Beyond that, the solver encounters overflow problems. For discussion of the computational instability of solving the matrix equations and alternative solution techniques, see Anick, Mitra, and Sondhi [Ref. 7:pp. 1873-1874]. The APL programs MATRIXE and MATRIXM were solved using APL2 on an IBM mainframe. Without increasing the workspace size beyond the default, it is possible to solve for systems of up to size 21 × 21; that is, where 21 is the number of both the maximum number of calls in progress and the maximum number of active calls in progress allowed (253)

states). It is possible to increase the size of the workspace from the default of 65% to a maximum of 85%, and thereby increase the size of the matrix which can be solved. However, it takes a long time to solve the larger systems, especially when creating tables of multiple runs.

## **B. APPROXIMATION**

The approximation routine APPROX, written in APL, calculates the limiting probabilities for both the Erlang and the multiplexer models. It may be found in Appendix D. The approximation routine is much faster than solving the sets of linear equations required to find the limiting distribution of the bivariate models. It is also able to solve larger problems, given the same APL workspace size. On the IBM mainframe APPROX can solve problems up to size  $32 \times 32$  (561 states) before encountering underflow errors in the results (due to extremely small limiting probabilities, on the order of 1E-75 or smaller). The approximation will solve for systems of up to C = 175(maximum calls in progress allowed) without halting due to domain errors (numbers larger than 1E75 in the intermediate calculations). Results from these larger systems may, however, be inaccurate due to the underflow errors mentioned above, depending on the value of A (number of physical channels). For instance, when solving for a system with C equal to 40, the approximation was able to calculate the results for as many as A = 33 channels before encountering underflow errors.

### C. VALIDATION OF THE COMPUTER CODE

# 1. Validating Code for the Erlang Model

The computer code was validated in two ways. First the results for one, two and three-channel systems were calculated by hand for a particular set of values for  $\lambda$ ,  $\mu$ ,  $\alpha$  and  $\beta$  to ensure that results matched those of the computer programs. Second, numerous cases were calculated using both the APL (MATRIXE) and the GAMS (ERLANG) programs to ensure that the two different programs yield the same results. The APL (APPROX) program for the Erlang model was then compared with results from APL (MATRIXE) to ensure that the approximation routine yields results which are close to the actual limiting probabilities.

## 2. Validating Code for the Multiplexer Model

The multiplexer codes (MUX in GAMS and MATRIXM in APL) were first validated by ensuring they yield the same results as the Erlang codes (ERLANG in GAMS and MATRIXE in APL) when all the same parameter values are used as inputs (i.e. no change in the service rate, no compression or packet header, and the number of channels J equals the maximum number of calls allowed K). The APL (MATRIXM) and GAMS (MUX) programs were also compared to each other to ensure the same results for various sets of input parameters. Results were also checked for internal consistency; that is, individual input parameter values were changed separately to check that the output values change as expected. Finally, the results of the APL (APPROX) program for the multiplexer model were compared with those of the APL (MATRIXM) program to check the validity of the approximation routine and determine the range of values over which the approximation yields results

close enough to be used as a tool in determining the reduction in bandwidth requirements.

#### VII. NUMERICAL RESULTS

### A. ACTUAL VS. APPROXIMATED BLOCKING PROBABILITIES

Results of several comparisons between the actual (MATRIXM) and approximated (APPROX) multiplexer model are shown in Appendix E. Comparisons were made for systems allowing a maximum of C = 5, 10, 15, 20, and 30 callers, assuming speech activity (average proportion of time a call in progress is active) of 35%. Traffic loads displayed depend on the value for C; the larger the value for C, the heavier the loads, though not larger than the value for C itself. This restricts the results, and analysis of those results, to the range of values for blocking probabilities which might be considered reasonable to plan for when designing a telecommunications system.

The results shown in Appendix E indicate that the approximated outer blocking (OUTBLA) becomes very close to the actual value (OUTBL) as the gap between A (number of channels) and C (maximum number of calls allowed) decreases. In fact, when A equals C, OUTBL and OUTBLA are also equal. The approximated inner blocking (INBLA) also becomes closer in value to actual inner blocking (INBL) as A and C become closer. The probability of inner blocking decreases, becoming zero when A equals C. The size of the limiting probability of inner blocking is, therefore, also closely linked to the difference between the actual and approximated outer blocking probabilities. As inner blocking decreases, OUTBLA becomes closer to the actual values. Note that there is a trade-off between outer and inner blocking.

Inner blocking increases as the gap between A and C increases, while outer blocking decreases.

The question is, at what point are the approximations close enough to the actual values to be used to determine limiting probabilities; that is, how close does A need to be to C? For inner blocking probabilities, the approximation results are extremely close to the actual values for even large relative gaps between A and C. For instance, when C = 5, 10, 15, 20, and 30, INBLA is accurate to 3 decimal places when A = 2, 3, 4, 4, and 5, respectively (for all traffic loads displayed). Also, when INBLA is accurate to 3 decimal places, the first 2 decimal places hold zeros. For the same values of C and the same traffic loads, OUTBLA is accurate to approximately 2 decimal places for A = 3, 3, 4, 4, and 5, respectively. Thus, INBLA is somewhat more accurate than OUTBLA and the size of the values for INBLA may be a good predictor of the accuracy of both INBLA and OUTBLA. Suppose we develop a 'thumb rule' that states: when INBLA is equal to zero in the first 'x' decimal places, (a) INBLA is accurate to within 'x+1' decimal places, and (b) OUTBLA is accurate to within 'x' decimal places. Close examination of the results in Appendix E indicate that our thumb rule is accurate for all values of C, A, and load shown, if the values for OUTBL are rounded to 'x' decimal places for comparison with OUTBLA. Thus, by using the approximated inner and outer blocking together, we can tell fairly accurately how close (within number of decimal places) OUTBLA is to the actual outer blocking probability by looking at the proportion of inner blocking.

As to answering the question posed, i.e. how close must A be to C for accurate results, the response depends on two things; (1) the level of accuracy

desired, and (2) the value of C. For telephone traffic engineering purposes, the level of accuracy necessary is generally 2 or 3 decimal places, so we want the values for INBLA to have zeros in at least the first 2 decimal places. Clearly, the ratio of A to C necessary for accurate results decreases as C gets larger.

Having developed a thumb rule methodology for determining the accuracy of the multiplexer approximation results without direct comparison with actual values, we may now look at the results of the approximation independently, allowing analysis of larger systems. The approximate results are much more quickly obtained, making it feasible to conduct multiple runs for different levels of speech activity. Analysis of these results, displayed in Appendix F, is the subject of the next section.

# B. SENSITIVITY ANALYSIS OF THE APPROXIMATED INNER BLOCKING PROBABILITIES

The approximation routine for the multiplexer model was run for different values of the initial mean length of a talkspurt,  $\beta^{-1}$ , and mean length of a silence,  $\alpha^{-1}$ , such that speech activity occupies 28 percent, 35 percent, and 42 percent of a call in progress. This was to determine sensitivity of the inner blocking probabilities (4) to changes in speech characteristics. Since the approximated outer blocking probability is calculated from the Erlang loss formula (2), it is not affected by any parameters other than  $\lambda$ ,  $\mu$ , and K.

The average length of a phone call,  $\mu^{-1}$ , was taken to be 180 seconds (3 minutes) for all runs. Speech activity rates considered were 28, 35 and 42 percent. The mean talkspurt and silence lengths are assumed to be 288 ms and 740 ms for the first case, 352 ms and 650 ms for the second case, and 420 ms

and 580 ms for the third case, respectively. Values for the last two cases are the same as those used by Sriram and Lucantoni [Ref. 14:pp. 703-712].

Results of runs for C = 5, 10, 20, 25, 30, 35, 40, 45, 50, 60, 70, 80, 90, 100, 125, 150, and 160 are given in Appendix F. To use the table in Appendix F, you first find the load (column 1) for which outer blocking probability (column 2) is less than or equal to a specified value, say 0.01. In the case of C = 20, the corresponding load is 12. The next three columns give the approximate inner blocking probability for speech activity rates of 28, 35, and 42 percent, respectively. The most conservative (highest) estimate of inner blocking would, of course, be found in the last column, representing the 42% activity level. If you wish a total blocking probability of no more than 0.01, accurate to within 2 decimal places, then you find the value of A for which, given a load of 12, the value for inner(42) is zero in at least the first 2 decimal places, and the addition of the outer and inner(42) blocking probabilities is closest to, but still no greater than, 0.01. Notice that we are not subtracting out the joint blocking probability (as on page 21) after adding together the inner and outer blocking probabilities. This is primarily because the joint blocking probabilities are so small as to be insignificant to the results of the calculations. Also, any error thus induced would be on the side of conservatism, and therefore tolerable. For this example, the value for A (number of channels) which meets the requirement is 5, which is one-fourth of the value for C (maximum number of callers).

Figure 5 shows a graphical representation of the data from Appendix F, for C = 20 callers and speech activity of 35%. It actually represents two graphs superimposed on each other. The one graph shows <u>outer</u> blocking probability

versus load when C (maximum number of callers allowed) is equal to 20. This is calculated using the Erlang loss formula (2). Curves for C<20 would be higher and to the left of the curve for C=20 (+ symbol); curves for C>20 would be lower and to the right. Graphs showing the curves for selected values of C ranging from 1 to 80 may be found in Cooper [Ref. 5, pp. 316-319]. Cooper uses different symbols and also uses a logarithmic scale for the blocking probabilities, which gives a different shape to the curves. The calculations and results, however, are the same. The other graph displayed in Figure 5 is inner blocking probability versus load for various values of A (A = 3, 4, 5, 6) when C=20 and speech activity is 35%. Remember that the value for A represents the number of channels (or equivalent bandwidth) available. The goal is to minimize the value of A while maintaining a specified standard of service; in this case, total probability of blocking no greater than .01.

From Appendix F we see that when C=20 and the load is 12 erlangs, the outer blocking probability equals .009796, and 12 is the highest load the system can take without exceeding the .01 limit on total blocking. Inner blocking can be no greater than .000204. We must find the value for A which satisfies this requirement. For speech activity of 35%, A=5 channels is sufficient, with inner blocking of .000148. Three channels is clearly too few, four channels will only work at the 28% level of speech activity, and six channels exceeds the standard of service required.

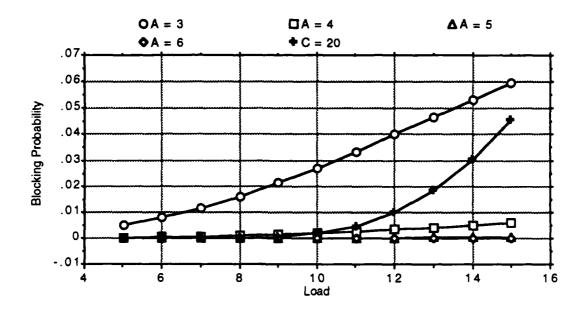

Figure 5. Outer Blocking Probability vs. Load for C = 20, shown with Inner Blocking Probability vs. Load for various values of A (given C = 20), assuming 35% speech activity. From Appendix F.

Given specific criteria for desired blocking probabilities and accuracy levels, we can make tables of the values for the load and for A necessary to meet those criteria for each value of C. Conversely, if the load is fixed, there is a specific value for C which will meet the desired blocking probability. We can also determine the magnitude of the effect that the proportion of speech activity has on the value of A chosen. Table 1 below is an example, where the desired total blocking probability (again ignoring joint blocking) is no greater than 0.01 and is accurate to within three decimal places. The data from Table 1 are graphically depicted in Figures 6 through 8.

TABLE 1. VALUES OF A FOR GIVEN LEVELS OF SPEECH ACTIVITY, WITH TOTAL BLOCKING NO GREATER THAN 0.010; ACCURATE TO 3 DECIMAL PLACES.

С	LOAD	A: INNER (28)	A. INNER (35)	A. INNER (42)
5	3	3	3	4
10	4	3	3	4
20	12	4	5	5
25	16	5	5	5
30	20	5	5	5
35	24	5	5	6
40	29	6	6	7
45	33	6	6	7
50	37	-6	6	7
60	46	6	7	7
70	56	7	8	8
80	65	7	8	9
90	74	7	8	9
100	84	8	9	10
125	107	8	9	10
150	131	9	10	11
160	141	9	11	12

Results of this study indicate that for low loads, the addition of multiplexers provides very little, if any, advantage in terms of reducing the number of channels necessary to provide acceptable blocking probabilities. The advantage increases dramatically as load increases. This is shown in Figure 6, where C and A represent the number of channels needed without and with multiplexers, respectively. Also, the level of speech activity does

have some impact on the number of channels required. However, the values of A for 35% speech activity are within ±1 channel of the values obtained for the lower (28%) and upper (42%) speech activity levels. This is shown in Figure 7, which gives a closer view of the bottom three lines from Figure 6. Figure 8 shows the use of regression analysis to interpolate the number of channels required for loads between those listed. The quadratic equation generated by the regression gives a model for predicting the value of A (on the Y axis) when the load (on the X axis) is known, given desired total blocking of no greater than 0.01 (accurate to within 3 decimal places) and speech activity of 35%. Note that since the information in Figures 6 through 8 is taken from Table 1, all three figures assume total desired blocking probabilties of .01. Once this is fixed, it fixes the value of C for every corresponding load, and vice versa. Therefore, the values given for A are dependent on the value of C as well as on the load, and C could be substituted for load on the X axis of the three graphs. The fact that load and C are dependent on each other allows us to use just the load to determine the value of A (number of channels needed for a multiplexed system) without doing the intermediate calculation to find the value of C (number of channels required for a non-multiplexed system), given, of course, that we know the desired total blocking probability and level of accuracy required.

#### VIII. CONCLUSIONS

In this study, we first developed stochastic models of a single-node telecommunications system both without and with the addition of an intelligent multiplexer (the bivariate Erlang and the Multiplexer models, respectively). The models were solved using matrix equations to compute the joint limiting probabilities for k callers and j talkspurts, as well as outer blocking and inner blocking probabilities (respectively the proportion of time the maximum allowed numbers of callers and talkspurts are in the system). Both GAMS (Appendices A and B) and APL (Appendix C) were used to do the computations for the purpose of validating the computer code.

Approximation routines (Appendix D) were then developed that were capable of performing the calculations much faster and for larger systems. Results from the multiplexer approximation were compared with the actual blocking probabilities computed from the matrix equations (Appendix E). A rule of thumb based on the size of approximate inner blocking probabilities was devised to determine the accuracy of both the approximate inner and outer blocking probabilities. Sensitivity analysis was also done to determine the effect of different levels of speech activity on the inner blocking probabilities (Appendix F). Given desired outer blocking and total blocking probabilities, as well as desired level of accuracy, it is possible to determine the number of channels (A) required to handle a particular traffic load in the multiplexer model, and compare this with the number of channels (C) required in the Erlang model.

Analysis of the results from the tables in Appendix F indicate that addition of a multiplexer significantly reduces bandwidth requirements, particularly for heavy loading. The multiplexer advantage decreases to the point of insignificance as the load becomes very small (less than 3). The point at which the addition of multiplexers becomes advantageous depends on the cost of the adding multiplexers to a network vs. the cost of leasing the additional channels or bandwidth. These costs are affected by the number of nodes in a network, the geographical distances between nodes, and the loading along the links between nodes. A lightly loaded network with many nodes which are close together will benefit less than a heavily loaded system with long distances between relatively few nodes.

This study does not compare model results with data from actual systems. Nor was the multiplexer model developed to fit data from a real system. The Erlang loss formula has been found to have much practical use in designing voice telecommunications systems which do not utilize intelligent multiplexers. It is hoped that the methodology employed to adapt the bivariate Erlang model to reflect particular multiplexer characteristics will likewise prove useful in determining bandwidth requirements for systems which use intelligent multiplexers. Further study is recommended to validate the multiplexer model through comparison with data from a multiplexed voice system. Adjustments to the model may also be made to reflect different performance characteristics and input parameter values.

## APPENDIX A

The following GAMS program computes limiting probabilities for the bivariate Erlang system. Results shown are for a three-channel system with the following characteristics:

Mean call length  $(\mu^{-1})$  of 3 minutes (180 seconds).

Load  $(\lambda \mu)$  equal to 1.

Mean talkspurt length ( $\beta$ -1) of 352 ms (.352 seconds)

Mean length of silence  $(\alpha^{-1})$  of 650 ms.

Speech activity of 35% ( $\alpha \div (\alpha + \beta) = 0.35$ ).

## APPENDIX D

The APL program APPROX calculates the limiting probabilities for both the Erlang and multiplexer models using approximation techniques. It calls the routine STATES to help format the output. BLOCK is used to compute the inner, outer, and combined inner-outer blocking probabilities for both the approximation (APPROX) and the actual (MATRIXM) calculations for comparison.

## APPENDIX E

These tables compare actual outer and inner blocking probabilities (OUTBL, INBL) with their approximated counterparts (OUTBLA, INBLA). Results are shown for C (maximum number of calls allowed) equal to 5, 10, 15, 20, and 30. The values for A indicate the number of available channels.

The level of speech activity (average proportion of time a call of infinite duration is active) is assumed to be 35% for all runs. The mean length of a call is 3 minutes. The mean length of a talkspurt ( $\beta^{-1}$ ) is 352 ms. The compression factor is 4-to-1 and the length of the header information is 15.625% of the mean length of a talkspurt. The rate of each active incoming channel is b = 32 Kbps. Thus, the value of  $(\beta^{-1})^*$  is 4576 bits. The outgoing channel rate s is equal to A, the number of available channels, multiplied by b, the incoming channel rate. The values for load  $(\lambda/\mu)$  are as indicated in the tables.

## APPENDIX F

The following tables show results of the approximation to the multiplexer model when C (maximum number of calls allowed) equals 5, 10, 20, 25, 30, 35, 40, 45, 50, 60, 70, 80, 90, 100, 125, 150, and 160. The values for A indicate the number of available channels.

Outer blocking probabilities are calculated from the formula for the truncated Poisson distribution (2). Inner blocking probabilities (equal to  $P_J(k)$ , from (6), where J=A) are compared for three different levels (28%, 35%, and 42%) of speech activity (average proportion of time a call of infinite duration is active). Mean talkspurt lengths ( $\beta^{-1}$ ) are assumed to be 288 ms. 352 ms. and 420 ms, respectively, for the three levels of speech activity. The compression factor is 4-to-1 and the length of the header information is 15.625% of the mean length of a talkspurt. The rate of each active incoming channel is b=32 Kbps. Thus, the values for ( $\beta^{-1}$ )\* are 3744, 4576, and 5460 bits, respectively, for the three levels of speech activity.

The mean length of a call is 3 minutes. The outgoing channel rate s is equal to A, the number of available channels, multiplied by b, the channel rate. The values for load  $(\lambda/\mu)$  are as indicated in the tables.
